Psychedelic drugs have long been known to be capable of inducing mystical or transcendental experiences, particularly at higher doses. However, given the common “recreational” nature of much present-day psychedelic drug use, with typical doses tending to be lower than those commonly taken in the 1960s, the extent to which illicit use of psychedelics today is associated with mystical experiences is not known. Furthermore the mild psychedelic stimulant MDMA (“ecstasy”) is more popular today than “full” psychedelics such as LSD or psilocybin, and the contribution of illicit MDMA use to mystical experiences is not known. The present study recruited 337 adults from the website and newsletter of the Multidisciplinary Association for Psychedelic Studies (MAPS), most of whom reported use of a variety of drugs both licit and illicit including psychedelics. Although only a quarter of the sample reported “spiritual” motives for using psychedelics, and such drugs were reportedly used only “rarely” by participants, psychedelic drug use (LSD and psilocybin) was significantly positively related to scores on two well-known indices of mystical experiences in a dose-related manner, whereas use of MDMA, cannabis, cocaine, opiates and alcohol was unrelated to mysticism scores. Further, only use of LSD, psilocybin or MDMA was significantly related to reports of ever having had an experience of an “overwhelming” nature. Results suggest that even in today’s context of “recreational” drug use, psychedelic drugs such as LSD and psilocybin, when taken at higher doses, continue to induce mystical experiences in many users.

KEYWORDS: LSD, psilocybin, MDMA, psychedelic drugs, mystical experiences, religious experiences
When taken in sufficient doses the psychedelic drugs LSD and psilocybin have been widely reported to elicit mystical or transcendent religious/spiritual experiences (e.g., Bakalar 1985; Griffiths et al., 2006; Harris, 2011; Hasler et al., 2004; Hofmann, 1983; Horgan, 2003; Leary, 1965; Maslow, 1964; Pahnke, 1963, 1969; Pahnke & Richards, 1966; Smith, 2000; Watts, 1965). Insights into God or Ultimate Reality, transcendence of the personal ego, merging with the cosmos and undergoing transformative death and rebirth are common elements of the mystical experiences reported by many of those who have taken high doses of LSD or psilocybin. Such reports resemble in some respects the classical descriptions of self-realization or enlightenment arising from the mystical traditions of major religions such as Buddhism and Hinduism (Grinspoon & Bakalar, 1979; Horgan, 2003; James, 1905; Suzuki, 1957; Watts, 1965).

Psychedelic drugs are potent direct serotonin agonists (Jacobs, 1987) that can induce powerful activation of the cerebral cortex, especially the prefrontal region (Vollenweider et al., 1997). Although the peak in popularity of psychedelics, particularly LSD, was in the 1960s, psychedelic drugs are still taken illicitly today but the purposes of present-day use can be quite different from the motives of typical LSD users in the 1960s. Today psychedelics are often used to enhance sensory experiences at concerts and dance parties - in contrast to the ego-transcending or “mind-expanding” goals of most psychedelics users in the 1960s. This change is reflected in the typical unit doses of LSD available on the black market today, which are considerably lower than the typical unit doses available in the 1960s (Laing & Siegel, 2003). Black market unit samples of LSD in both the U.S. and Europe in the 1960s often contained several hundred micrograms (erowid.org/chemicals/lsd/lsd_history1.shtml), a dose range characterized as “strong” or “heavy” by the popular drug use information website erowid.org; by contrast in the past decade typical black market LSD unit doses averaged only about 50 micrograms (Hidalgo,
Pahnke (1963) and Griffiths et al. (2006) demonstrated that a strong dose of psilocybin administered in a controlled, supportive experimental setting can induce profound mystical experiences in drug-naïve subjects, with self-reported transformative effects for some that lasted decades (Doblin, 1991). The present study examined mystical experiences in relation to illicit drug use among a sample of “recreational” psychedelic and other drug users. Given that psychedelic drug dose is said to be a crucial factor influencing whether an occasion of use is capable of catalyzing a transformational mystical experience, we expected to find that the usual dosage taken as reported by users for the full psychedelics LSD and psilocybin, but not MDMA or non-psychedelic drugs such as cannabis, cocaine, opiates or alcohol, would be positively related to self-reported mystical experiences as well as to experiences of an “overwhelming” nature. Scores on the Depression Anxiety and Stress Scales (DASS-21) served as a control for the potential influence of mild psychopathology on such self-reports. In addition, self-report measures of specific life values and empathy were examined as a previous cross-cultural study found that psychedelic drug users rated the life values of spirituality, creativity, concern for the
environment and concern for others more highly than did non-users (Lerner & Lyvers, 2006), a difference which the authors speculated might be a result of mystical experiences in the former group. Mindfulness was also examined given the foundation of that concept in the mystical Zen Buddhist tradition (e.g., Maezumi & Glassman, 2007).

Method

Participants

Participants were recruited online from members of the Multidisciplinary Association for Psychedelic Studies (MAPS) and those who visited its website (www.maps.org). MAPS is a nonprofit organization promoting research on potential medical and psychiatric applications of marijuana and psychedelic drugs. A monthly newsletter emailed to MAPS members contained a brief description of the online survey and a link to it. This information was also placed on the MAPS website. The total number of participants who completed the survey was 350, with 337 providing usable data. Among these 337 participants, ages ranged from 16 to 79 years (M = 29.12 years, SD = 12.14), and 68.5% were male. The majority (68%) reported having a university degree; 32% of participants were students, and 58% of participants were employed full-time.

Approval was obtained from the Bond University Human Research Ethics Committee prior to the commencement of the study. No incentive was offered for participation.

Materials

To commence the online survey administered via Survey Monkey, each participant had to read an explanatory statement which assured them of the anonymity of their data, and informed them of their right to withdraw from the study at any time without consequence. The following questionnaires comprised the survey.
Demographics and drug use questionnaire. This measure was created for this study and asked for the participants’ age, gender, education, occupation, and personal history of use of alcohol and illegal drugs including cannabis (marijuana), MDMA (ecstasy), cocaine, opiates, LSD and psilocybin. Participants were asked to estimate their frequency of use on a six-point scale where 0 = “never,” 1 = “daily,” 2 = “weekly,” 3 = “fortnightly,’ 4 = “monthly’ and 5 = “rarely.” They were also asked to estimate their usual dosage taken on a four-point scale where 0 = “none,” 1 = “low dose,” 2 = “common dose,” and 3 = “strong dose.”. Participants were also asked if they had ever had an overwhelmingly intense experience of any kind - not necessarily drug induced but could include drug experiences – by ticking either “yes” or “no.” For those who indicated they had used psychedelics, a question asked for the participant’s motives for such use.

Mysticism Scale (Hood, 1975). This 32-item questionnaire contains items that ask participants about past mystical experiences (if any). The Mysticism Scale has been used in research on the psychology of religion (Spilka, Hood, Hunsberger & Gorsuch, 2005) but has only previously been applied to drug experiences by Griffiths et al. (2006), who used it to assess psychedelic drug (psilocybin) experiences. The Mysticism Scale yields a total score based on three dimensions of mystical experience: noetic quality (e.g., “I have never experienced anything to be divine,” reverse-scored); introvertive mysticism (e.g., “I have never had an experience which I was unable to express adequately through language,” reverse-scored); and extrovertive mysticism (e.g, “I have had an experience in which I felt everything in the world to be part of the same whole”). The items are rated on a nine-point scale ranging from −4 = “this description is extremely not true of my own experience or experiences” through 0 = “I cannot decide” to +4 = “this description is extremely true of my
own experience or experiences.” The psychometric properties of this scale have been reported to be sound (Reinert & Steifler, 1993).

*States of Consciousness Questionnaire* (SCQ; Griffiths et al., 2006). The SCQ contains 100 items pertaining to states of consciousness and mood, but only the 43 items of the Pahnke-Richards Mystical Experience Questionnaire (*MEQ*; Pahnke, 1969; Richards, 1975) are scored, with the remainder being distractor items. The MEQ was used in Pahnke’s 1966 Good Friday experiment as well as in the subsequent psilocybin study by Griffiths et al. (2006), the latter in the form of the SCQ as in the present study. The MEQ assesses experiences of internal unity, external unity, transcendence of time and space, ineffability, paradoxicality, sacredness, noetic quality, and positive mood. Participants rated each statement on a six-point Likert scale for degree of having experienced the phenomenon listed, from 0 = “not at all” to 5 = “extreme.” A sample item is “sense of profound humility before the majesty of what was felt to be sacred or holy.” Total scores can range from 0 to 215.

*Balanced Emotional Empathy Scale (BEES; Mehrabian, 1996).* This scale assesses one’s perceived ability to identify and feel the emotions of others. Participants rate 30 items on a nine-point Likert scale where -4 = “very strong disagreement,” 0 = “neither agreement or disagreement,” and +4 = “very strong agreement” with each item. A sample item is “I am moved deeply when I observe strangers who are struggling to survive.” Research has indicated that the BEES has good to excellent internal consistency, convergent validity and predictive validity (Mehrabian & Epstein, 1972; Mehrabian, Young & Sato, 1988).

*Life Values Inventory (LVI; Crace & Brown, 1996).* The LVI uses 42 items to measure 14 different life values that are rated for personal importance on a five-point Likert scale, where 1 = “almost never guides my behavior,” 3 = “sometimes guides my behavior” and 5 = “almost
always guides my behavior.” The 14 life values are achievement, belonging, concern for the environment, concern for others, creativity, financial prosperity, health and activity, humility, independence, loyalty to family or group, privacy, responsibility, scientific understanding, and spirituality. Brown and Crace reported high test-retest reliability for the 14 life values ranging from .78 to .97. For the purpose of this study only creativity, spirituality, concern for the environment, and concern for others were examined, based on previous findings described earlier above (Lerner & Lyvers, 2006).

Langer Mindfulness Scale (LMS; Langer, 2004). The LMS assesses the construct of mindfulness as practiced in everyday life. Participants rate 21 items in reference to their personal outlook on a five-point Likert scale where 1 = “strongly disagree,” 3 = “neutral,” and 5 = “strongly agree.” There are four subscales, novelty-seeking, engagement, novelty-producing, and flexibility; as these have been found to load onto a single scale score, only the total score was used in the present study.

Depression Anxiety and Stress Scales (DASS-21; Lovibond & Lovibond, 1995). The DASS-21 is comprised of 21 items concerning negative mood states experienced in the past week, rated using a four point Likert rating scale where 0 = “these statements did not apply to me at all,” 1 = “applied to me some of the time,” 2 = “applied to me a good part of the time,” and 3 = “applied to me most of the time.” There are three subscales, Depression, Anxiety and Stress. Items include “I just couldn’t seem to get going” (Depression), “I found it difficult to relax” (Anxiety) and “I found it hard to wind down” (Stress). Normal scores for Depression are 0-9, Anxiety 0-7, and Stress 0-14 (Lovibond & Lovibond, 1995), with higher scores indicating psychopathology. The psychometric properties of this widely used measure are regarded as excellent (Crawford & Henry, 2003).
Procedure

Participants completed the questionnaires anonymously online via Survey Monkey. Once participants opened the link to the present survey on the computer that he or she used, they first read the explanatory statement. Then, participants clicked “Next,” which directed them to the demographics questionnaire. After the completion of this section, participants proceeded to the other questionnaires. Upon completing the last questionnaire, participants clicked “Finished,” which brought them to a thank you and appreciation page.

Results

After removal of multivariate outliers and cases with substantial missing data from the dataset, 337 cases remained to provide usable data. Of these 337 participants, 99% reported having used alcohol, 58% reported having used cocaine, 40% reported having used opiates, 96% reported having used cannabis, 74% reported having used MDMA, 83% reported having used LSD, and 89% reported having used psilocybin. The very high proportions of the sample who reported having used cannabis and psychedelics was expected given the nature of MAPS as an advocacy group promoting potential beneficial applications of these substances. However, estimated self-reported frequency of drug use was low in this sample except for use of alcohol and cannabis. The most commonly reported frequency of use for alcohol was “weekly” (35%), whereas for cannabis the most commonly reported frequency of use was “daily” (44%). By contrast, “rarely” (less than monthly) was the most commonly reported frequency of use for cocaine, opiates, MDMA, LSD and psilocybin in this sample. Self-reported doses taken showed a broader distribution than frequency of use, although “common” was the most frequently cited dose level with frequencies ranging from 13% to 45% for this dose category; the exceptions were cocaine and opiates, for which the most commonly cited quantity was “none” (these drugs...
having the lowest proportion of users in the sample; see above). DASS Depression, Anxiety and Stress scores were quite low in this sample, averaging only 3-4 out of a possible 21. Among those who reported having used psychedelics and provided motives for use, the most common self-reported motive for use was “mind expansion” (41%), followed by “spiritual” (25%), “curiosity” (13%) and “recreation” (7%), with the remainder citing “other.”

Intercorrelations among the measures of interest were calculated and are presented in Table 1. Illicit drug doses were all intercorrelated as expected, such that self-reported use of higher doses of any one drug were associated with self-reported use of higher doses of other drugs as well. LSD dose was significantly positively correlated with scores on the Mysticism Scale, MEQ, and LVI Creativity. Psilocybin dose was significantly positively correlated with Mysticism and MEQ scores. The other illicit drugs (cocaine, cannabis, opiates, MDMA) showed only small to no correlation with any of the scales, and none with Mysticism or MEQ scores. Alcohol dose was significantly negatively correlated with BEES empathy scores and three of the five LVI values, environmental concern, concern for others, and spirituality. Participant age was significantly negatively related to all self-reported drug doses except cocaine, and significantly positively related to BEES empathy, LVI environmental concern and LVI spirituality.

Several of the scales were significantly intercorrelated in expected ways. For example, BEES empathy scores were positively correlated with LVI concern for others; LVI spirituality scores and LMS mindfulness were positively correlated with each other and with Mysticism, MEQ, BEES, and LVI concern for others, creativity and environmental concern; and the DASS scales were all intercorrelated as usual (e.g., Lyvers et al., 2009) although interestingly they did not significantly correlate with any other measure including drug use indices (see Table 1).
Hierarchical regression was used to assess predictors of the primary criterion measures of interest, i.e., Mysticism Scale scores and MEQ scores, examining the possible roles of LSD and psilocybin dose after controlling for demographic variables, mood variables, and self-reported doses of drugs other than LSD or psilocybin. In these regressions age, gender and education level were entered at step 1, followed by DASS Depression, Anxiety and Stress scores at step 2, self-reported doses of alcohol, cannabis, cocaine, opiates and MDMA at step 3, and self-reported doses of LSD and psilocybin at step 4. For prediction of Mysticism Scale scores the regression model was only significant at step 4, $F(13, 291) = 2.79, p < .001$; the addition of psychedelic drugs at step 4 accounted for 11% of the variance in Mysticism Scale scores, $F_{\text{change}}(2, 291) = 10.60, p < .0001$. The only significant drug predictors of Mysticism scale scores were LSD dose, $\beta = .23, p < .0001$, and psilocybin dose, $\beta = .13, p = .04$. No other predictors approached significance except for age at step 4 only, $\beta = .14, p = .02$. For MEQ scores as the criterion the results were very similar; again the regression model was only significant at step 4, $F(13, 291) = 3.12, p < .0001$, and the addition of psychedelic drugs at step 4 explained 12% of the variance in MEQ scores, $F_{\text{change}}(2, 291) = 12.60, p < .0001$. The only significant drug predictor in the final model was LSD dose, $\beta = .26, p < .0001$, with psilocybin dose approaching significance, $\beta = .11, p = .07$, and age again significant at step 4 only, $\beta = .13, p = .03$.

Finally, among drug use variables, only use of drugs with psychedelic properties was significantly related to the report of having ever had an overwhelming experience. Among those who reported ever using LSD ($n = 280$), 89% responded “yes” to the question asking whether they had ever had an overwhelmingly intense experience of any kind, compared to only 68% of those who said they never tried LSD ($n = 56$), a significant association, $\chi^2(1) = 15.81, p < .0001$. Similarly, among those who reported ever using psilocybin ($n = 299$), 89% reported having had
an overwhelming experience versus only 59% of those who said they had never tried psilocybin ($n = 37$), again a significant association, $\chi^2(1) = 21.61, p < .0001$. By contrast there was no relationship between use of the non-psychedelic drugs alcohol, cocaine, opiates, and cannabis with having ever had an overwhelming experience, all $p > .20$; however use of MDMA, a drug with mixed stimulant and mild psychedelic properties, was significantly related to the report of an overwhelming experience, $\chi^2(1) = 14.96, p < .0001$. Of those who said they had tried MDMA ($n = 249$), 85% reported having ever had an overwhelming experience compared to 72% of those who said they had never taken MDMA ($n = 87$). However, use of MDMA was strongly related to use of LSD, with 90% of those who reported ever using MDMA also reporting use of LSD versus only 61% of those who reported never using MDMA, $\chi^2(1) = 41.00, p < .0001$; nearly identical results were obtained for self-reported use of psilocybin by those who reported use of MDMA versus those who did not, $\chi^2(1) = 28.67, p < .0001$. Therefore the reports of overwhelming experiences by MDMA users may reflect their use of LSD or psilocybin rather than MDMA. In an attempt to assess this, MDMA use was examined in relation to reports of an overwhelming experience among the 15 participants who said they had never tried LSD or psilocybin, 10 of whom reported never using MDMA versus 5 who reported MDMA use. In this subgroup there was no significant association between MDMA use and reports of an overwhelming experience, $\chi^2(1) = 1.25, p = .26$, however given the very small size of this subgroup the lack of significance is not surprising. Of those who said they had used MDMA, 3 out of 5 reported having ever had an overwhelming experience versus only 3 out of 10 of those who reported never using MDMA. By contrast among those 57 participants who reported never using LSD, psilocybin use was significantly related to reports of ever having had an overwhelming experience, $p < .01$; likewise among the 37 who reported never using psilocybin,
LSD use was significantly related to reports of ever having had an overwhelming experience, \( p < .05 \).

**Discussion**

Results were in line with predictions for the two indices of mystical experiences, the Mysticism Scale and the MEQ, the variances of which were significantly explained by self-reported dose of LSD or psilocybin but not of other drugs. Furthermore, the self-report of having ever had an overwhelming experience was significantly associated only with self-reported use of drugs with psychedelic properties, i.e., LSD, psilocybin, and MDMA, although the latter association may reflect the extremely high overlap between MDMA users and users of the “full” psychedelics LSD or psilocybin in this sample. Mysticism Scale and MEQ scores were significantly highly positively correlated with each other and with all four LVI values (environmental concern, concern for others, creativity, and spirituality) as well as with BEES empathy and LMS mindfulness, consistent with expectations based on the mystical traditions of Buddhism and other religions according to which such values, as well as mindfulness, can be lasting sequela of mystical enlightenment. However, aside from a small positive correlation between self-reported LSD dose and LVI creativity, there were no significant relationships between self-reported dose of any illicit drug – including psychedelics - and the other LVI values tested, nor with BEES empathy or LMS mindfulness. Alcohol dose was negatively related to BEES empathy and LVI environmental concern, concern for others, and spirituality.

The vast majority of the current sample of MAPS members and those who visited the MAPS website reported use of psychedelic drugs. This was expected based on the mission of MAPS, a nonprofit organization dedicated to supporting medical and psychiatric applications of psychedelic drugs as well as MDMA and cannabis. However, the vast majority reported only...
“rare” (i.e., less than once per month) use of such drugs; 74% of LSD users said they “rarely” used LSD, 77% of psilocybin users said they “rarely” used psilocybin, and 69% of MDMA users said they “rarely” used MDMA. This was in contrast to cannabis users, 44% of whom reported “daily” use. Despite the low frequency of use of psychedelic drugs in the sample, self-reported psychedelic dose predicted scores on the two mystical experiences questionnaires as per expectations. The most commonly cited reason given for psychedelic drug use was “mind expansion,” although a quarter of psychedelic drug users cited “spiritual” reasons for use. Present findings indicate that, although the 1960s have long passed and black market LSD unit doses have dramatically declined, illicit use of psychedelic drugs LSD and psilocybin is still significantly associated with experiences that can be characterized as mystical, transcendental or spiritual in nature, a relationship which appears to be dose-dependent. Self-reported doses of the quasi-psychedelic drug MDMA, on the other hand, did not predict such experiences in this sample, nor did any other drug examined.

Although LSD and psilocybin have long been recognized as capable of inducing mystical experiences, Horgan (2003) suggested that, as yet, no “psychedelic saints” have emerged from the psychedelic user subculture. Horgan’s comment begs the question of how to determine “sainthood” outside of an established religious tradition such as Catholicism. Lerner and Lyvers (2006) found that users of psychedelics such as LSD or psilocybin differed from users of non-psychedelic drugs such as cannabis in terms of higher empathy scores and higher scores on LVI creativity, spirituality, concern for others and concern for the environment in the former group. The authors speculated that such differences may in part have resulted from psychedelic mystical experiences in the former group. However, in the present study the strong positive relationships between self-reported dose of LSD or psilocybin and scores on the two mystical experience
questionnaires, coupled with the lack of relationships between psychedelic drug dose and scores on empathy, spirituality, concern for others and concern for the environment, suggest a different interpretation. For various reasons those who choose to use psychedelic drugs may on average place greater value on empathy, concern for the environment, creativity, and spirituality than those who do not choose to use psychedelics, as previously found by Lerner and Lyvers in both Israel and Australia, but the present results do not suggest that those differences specifically arise out of psychedelic-induced mystical experiences. Rather the group differences found by Lerner and Lyvers likely reflect the self-selected nature of psychedelic users and their associated subculture, which even today may share many of the values of the “hippie” movement of the 1960s. In mystical religious traditions perhaps the posited relationship between non-drug-induced spiritual enlightenment and “saintly” values – exemplified by the Mahayana Buddhist ideal of the enlightened Bodhisattva as one dedicated to reducing the suffering of all sentient beings - may to a significant extent reflect the nature of the person who undertakes such a rigorous mystical quest through traditional means, typically requiring many years of highly demanding sacrifices and self-discipline in search of ultimate truth, rather than the transient mystical experience of enlightenment per se (Harris, 2011).

The present findings that higher self-reported doses of the psychedelic drugs LSD and psilocybin were associated with higher scores on two indices of mystical experiences should not be interpreted as encouraging psychedelic drug use, much less use of high doses. Although both LSD and psilocybin are physically very safe, the psychological hazards of uncontrolled use can be quite high, as was demonstrated in the 1960s when uncontrolled LSD use was widespread (e.g., Cohen, 1970). Panic reactions and “bad trips” followed by post-traumatic stress symptoms such as “flashbacks” were widely reported among casual users of psychedelic drugs in the 1960s,
although such reactions tend to be much rarer when the drugs are taken by psychologically stable, mature participants in a supportive, controlled environment - as in the recent study by Griffiths et al. (2006). Nevertheless even in the latter experiment about one third of participants reported “significant fear” (p. 15) during their psilocybin experience. Griffiths et al. noted that under uncontrolled conditions such reactions might easily lead to irrational behavior that could be dangerous to the user or to others. Given the unpredictability and intensity of psychedelic drug effects, such drugs should never be taken casually. Any future licit applications of such drugs are likely to be restricted to highly controlled circumstances involving careful screening, preparation and support of those who take these substances for a specific purpose, whether medical or spiritual.
